(54) Title: A METHOD FOR THE REMOVAL OF CAUSATIVE AGENT(S) OF TRANSMISSIBLE SPONGIFORM EN- CEPHALOPATHIES FROM PROTEIN SOLUTIONS (57) Abstract For separating non-conventional transmissible agents (NCTAs), i.e. causative agent(s), of transmissible spongiform encephalopathies (TSEs) from a solution of a protein susceptible to contamination with NCTAs, particularly from blood products, at least one adsorbent is suspended, for a time of at least 10 minutes. The adsorbent is selected from kieselguhr, diatomaceous earth, silicic acid, clay minerals, metal hydroxide, metal oxihydrate, cellulose, perlite, bentonite, and water-insoluble synthetic polymers. The obtained suspension is agitated, and subsequently the adsorbent is separated from the protein solution.		

A METHOD FOR THE REMOVAL OF CAUSATIVE AGENT(S) OF TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES FROM PROTEIN SOLUTIONS

The present invention concerns a method for the removal of the
5 causative agent(s) of transmissible spongiform encephalopathies (TSEs) from
protein solutions, particularly from blood products that will be used for
therapeutic and other medical purposes. The protein solution is brought into
contact with an adsorbent to which the agent(s) will be bound.

10 In world war II a method was developed in the USA for the isolation
of proteins from human blood plasma. These isolated proteins are used
medically as therapeutic agents. Albumin, immunoglobulins, fibrinogen,
coagulation factors and numerous other proteins are examples of products of
this method. Albumin is used, e.g., for burn patients or more generally in
15 diseases in which the blood volume has to be increased. Immunoglobulins may
be used in patients who are not able to synthesize protective antibodies
themselves. Coagulation factor concentrates (in particular factor VIII and factor
IX) are being used for hemophilia patients. In many cases these preparations
are life-saving and therefore they have no substitute.

The methods for the separation of blood plasma in individual proteins
20 are based on several different principles. The older methods which are still
being used on a large scale are based on fractional precipitation of the proteins
with ethanol and subsequent separation of the phases by centrifugation or
filtration. In newer fractionation schemes, other separation methods are used as
well, e.g., ion exchange chromatography or (immune) affinity chromatography.
25 An integrated separation scheme usually comprises several different methods
which are combined in an optimized process.

In the first years of use of plasma proteins in humans it became clear
that products made from human blood also have disadvantages: they may
transmit some infectious diseases which are caused by viruses. The most
30 important virus in the beginning was viral hepatitis (hepatitis B). Later on other
forms of hepatitis became known (non-A non-B hepatitis which was recently

identified and named hepatitis C). The best known virus which is transmitted by blood and blood products is the HIV (Human Immunodeficiency Virus), the causative agent of AIDS (Acquired Immune Deficiency Syndrome). Apart from those mentioned so far, there are some other viruses that may also be
5 transmitted by plasma and plasma derivatives.

In recent years other transmissible diseases with some common features became known. They are called TSEs and believed to be transmitted by non-conventional transmissible agents (NCTA). The human diseases Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker disease
10 (GSS), fatal familial insomnia (FFI), and kuru all belong in this group, as do some animal diseases, the best known of which are scrapie in sheep and bovine spongiform encephalopathy (BSE; „mad cow disease“) in cattle. Affected humans and animals all show symptoms of neurodegeneration and the diseases are invariably fatal. CJD, the best known human disease in this group,
15 most often develops sporadically; in some cases, however, clustering in certain families was observed. Iatrogenic transmissions through pituitary gland extracts, contaminated instruments used in neurosurgical procedures, and transplantation of cornea or dura mater has also been described. A transmission of any of the human diseases by blood transfusion has never been
20 shown. A retrospective epidemiological study among recipients of transfused blood did not show an increased rate of CJD when compared with non-transfused controls [T.F.G. Esmonde, R.G. Will, J.M. Slattery et al.: Creutzfeldt-Jakob disease and blood transfusion. Lancet 1993, 341: 205-207]. A look-back among recipients of erythrocyte concentrates donated by a man who later on
25 died of confirmed CJD did not show a single case of abnormal neurological or psychiatric findings [N. Heye, S. Hensen, N. Müller: Creutzfeldt-Jakob disease and blood transfusion. Lancet 1994, 343: 298-299]. Transmission of TSEs by blood transfusion must therefore be either extremely rare or extremely inefficient or both. The public and the regulatory authorities are nevertheless
30 aware of a potential problem, and need reassurance that utmost care is exercised to protect the patients from a possible exposure to NCTAs.

The existence of an infectious agent is proven beyond the shadow of a doubt. The exact nature of this agent is, however, still debated. In the past,

most researchers believed the disease to be caused by a slow virus; the more popular hypothesis now is that the infectious agent is a proteinaceous particle which may or may not contain nucleic acid, a so-called prion. Prions occur in at least two different forms, one normally found in cells which is called PrP^c, and
5 another form which only occurs in individuals affected by the disease which is called PrP^{sc} or PrP^{res} for its association with scrapie or for its resistance to degradation by proteases, most notably protease K. The difference between PrP^c and PrP^{res} is brought about by changes in folding, or tertiary structure, of the protein, a predominantly α -helical conformation being changed mostly to β -
10 sheets. PrP^{res} is associated with, or may be the cause of, the TSEs. The involvement of other factors (cofactors, i.e., nucleic acids, other proteins) is also being discussed.

The safety of blood and blood derivatives may be increased by 5 measures taken on different levels: (1) the collecting agencies try to exclude
15 donors who are known to pose a high risk for transmitting infectious diseases. This is done with the aid of a questionnaire which allows exclusion of people with increased risk factors. Persons with increased risk factors are, e.g., those who suffer from certain diseases, those who visited certain countries shortly before donation, those who incur risks through their sexual activity or drug
20 addicts who use contaminated needles, recipients of corneal or dura mater transplants, people who have been treated with pituitary hormones or who have CJD-cases in their family. (2) Laboratory analyses allow the determination of infectious donations which can then be removed from further processing. Those two measures taken together result in removal of most infectious donations but
25 not all: (a) the sensitivity of the test methods may be insufficient; (b) a test for a particular infectious agent may not yet be available; for practical and economic reasons it is not possible to screen for all potential infectious agents; (c) the test does not detect the infectious agent itself, but rather the antibodies that are elicited in the infected person as a response to the infection. From the time of
30 infection until detectable antibodies appear, usually a few days or weeks elapse (so called window). Antibody tests are useless during this period; (d) an infected donation may be released because of a clerical error. (3) The safety with respect to transmission of infectious agents is further improved by special steps that are introduced into the production process which either inactivate or

- eliminate infectious agents. (4) Strict adherence to good manufacturing practice (GMP) guarantees the efficiency of the steps mentioned under (3). (5) Full traceability of every donation to the corresponding products and from the final products back to the individual donation allows directed recalls of products, should this become necessary.

- Methods for detection, inactivation, and elimination of infectious viruses in blood and plasma products are now widely established. Commercial detection systems are used world-wide for detecting, e.g., antibodies to human immunodeficiency virus or to hepatitis C virus. Inactivation of viruses may be achieved by various heat treatments (either in solution or in the dry state; at different temperatures and for different periods of time), by chemical (with a combination of solvents and detergents or with iodine), or photochemical treatments (e.g., exposure to γ -propiolactone and ultraviolet light; illumination of a protein solution to which a suitable dye has been added), or by any of many other well known methods. New methods are still being developed. Transmission of known viruses by pharmaceuticals produced from human plasma can nowadays be ruled out with almost complete certainty, transmission of unknown viruses is at least highly unlikely.

- The situation is, unfortunately, more difficult with NCTAs. Blood donors are routinely asked questions aimed at eliminating those with an increased risk of contracting CJD later in their life (have family members ever suffered from CJD or similar diseases? Has the donor ever been exposed to pituitary hormones or to a corneal/dura mater transplant?). There is no doubt that this line of questioning may eliminate some of the potential iatrogenic and familial cases, but it will not affect the potential sporadic cases. Elimination of high-risk donors by questioning is therefore at best haphazard, and it is predictable that many cases will slip through. Screening of the donations is not yet possible. Although monoclonal antibodies have been developed which recognize PrP, most do not distinguish between PrP^c and PrP^{res}; the assay would therefore have to incorporate a protease digestion, which makes it too cumbersome for routine use. Even worse, it is not at all sure whether PrP^{res} is to be found in blood or plasma; the better source for a tissue specimen would be a brain biopsy, which is clearly not possible with blood donors. It might be pos-

sible to develop an assay based on a newly described monoclonal antibody which reacts specifically with PrP^{res} [Korth *et al.*: Prion (PrP^{Sc})-specific epitope defined by a monoclonal antibody. Nature 1997, 390: 74-77]; however, this has not yet been done.

- 5 Unfortunately, the agent(s) of TSE are uncommonly stable against inactivation. The methods mentioned above for the inactivation of viruses do not diminish the infectivity of NCTAs. As a matter of fact, they even survive autoclaving (steam treatment at 121°C for 15 min) and burial in the ground for several years. Few conditions are known to reliably inactivate NCTAs:
- 10 autoclaving at increased temperature ($\geq 134^\circ\text{C}$ for at least 18 min; treatment with 1 Mol/L of sodium hydroxide solution, preferably at elevated temperatures; strongly oxidizing conditions (sodium hypochlorite); strongly chaotropic conditions (guanidinium isothiocyanate). If such conditions were used on a solution of human plasma proteins, the proteins themselves would be
- 15 inactivated at least as rapidly as the NCTAs. The only alternative appears to be physical removal of the NCTAs. Since the monomers of the infectious compound(s) may be of similar size as human plasma proteins, they cannot easily be removed by, e.g., (nano)filtration or centrifugation. It has indeed been shown that nanofiltration was able to remove NCTAs, but that the removal
- 20 depended on the presence or absence of certain solutes; e.g., the infectious agents passed through the filter in the presence of surfactants.

- Companies that process human blood or blood plasma therefore have the need for industrially applicable methods that allow a safe removal of NCTAs from protein solutions. In order to minimize the theoretical risk of
- 25 infection for the patients who are treated with such products, it is thus the aim of the present invention to describe a method which allows the separation of NCTAs from protein solutions on an industrial scale; this method may be part of any current plasma fractionation scheme.

- The object of the present invention is therefore to provide a method
- 30 for a safe removal of NCTAs from solutions of protein susceptible to contamination with NCTAs.

bentonite, or in general finely distributed solids which can be removed by filtration or centrifugation from a suspension. Substances like metal hydroxide gels (e.g. Alhydrogel $\text{Al}(\text{OH})_3$ as a gel in water) are also suitable.

The adsorption of NCTAs on the materials mentioned depends on
5 the material used, the NCTA, and the environment. By systematic change of the environment, the "stickiness" of a particular NCTA onto the same material may be changed. It may be possible to modify the adsorption of NCTAs to a particular material by, e.g., changing the pH-value of the medium. Other solution parameters like temperature, ionic strength, salts, and organic solvents
10 may also influence the adsorption of NCTAs and may be used in order to improve adsorption and therefore the removal of NCTAs from the protein solution.

Even a short treatment of the protein solution for only 10 minutes can result in a substantial removal of NCTAs. It may, however, be advantageous to treat for a longer time in order to improve removal of NCTAs. Treatment times
15 may be approximately 15 min, 30 min, approx. 1 h, approx. 2 h, approx. 6 h, approx. 8 h, approx. 12 h, ca approx. 14 h, approx. 16 h, approx. 20 h.

The removal of the adsorbent including the adsorbed NCTAs is done either by centrifugation or filtration. Centrifugation may be done in different ways, e.g., by a batch procedure or a continuous centrifugation. Centrifugal
20 force and time of centrifugation have to be adjusted so that a clean separation of suspended material and supernatant is guaranteed. On a laboratory scale, filtration may be carried out with a Büchner funnel or a similar apparatus. On larger scale (production) other equipment is preferred, e.g., filter presses or rotating filters.

Experimental

For obvious reasons, it is not possible to conduct experiments with the causative agent(s) of CJD or similar human diseases in man. In order to learn something about the behavior of NCTAs it is therefore necessary to resort to model systems. One well established model system is a hamster scrapie model. The following is a brief description of the model: First, an inoculum is prepared from the brain of a diseased animal; the brain is removed carefully and homogenized by sonication with 9 volumes of phosphate buffered saline. This preparation can transmit the disease when 50 μ L are inoculated intracranially into healthy hamsters. Depending on the potency of the inoculum, disease will develop within a few weeks or several months. All animals have to be observed for a year or until they die, whichever comes first. The disease manifests itself by characteristic behavioral changes, e.g., increased response to noise and ataxia. By diluting the inoculum in steps of 1 in 10 with buffer and inoculating the dilutions into animals, it is possible to define a titer of the inoculum; the titer is the reciprocal of the last dilution which caused disease in half the animals that were inoculated. An inoculum prepared as described above has a titer of about 10^{12} . The advantage of this model is that it does not make any assumptions concerning the nature of the infectious agent(s), since the assay relies on clinical disease. The infectious agent(s) may therefore be one or more proteins, with or without nucleic acid(s) involved, a slow virus or any other entity, it is always the infectious agent(s) which are measured. This system may therefore be used to assess either the physical removal or the inactivation of the causative agent(s) of TSEs. Experiments are carried out in analogy to validation experiments with viruses, which have been described in detail in the literature for the past approximately ten years: a small amount of the infectious material (the so-called spike) is added at a particular step of the purification process of the product under evaluation and its activity is measured. The next process step is then performed (e.g., a precipitation, followed by separation of precipitate and supernatant; a thermal inactivation) and the remaining activity is titrated, in both phases in the case of physical separation, or as a function of time in the case of inactivation. Inactivation factors can be calculated from these measurements, provided the balance sheet tallies or the kinetics were followed correctly. In the case of NCTAs titration is extremely

cumbersome, because every titration point requires the use of several animals; the protocols have therefore to be amended accordingly. The outcome of the experiments is only known after several months, when the infected animals will either have contracted the disease or remained healthy.

5 Examples

The brain homogenate used in all the following examples was carefully titrated by injecting dilutions into hamster brains. After 187 days of observation, the distribution of sick and healthy animals in the different cohorts was as follows:

dilution	challenge 1	challenge 2
10^{-1}	4/4	4/4
10^{-2}	4/4	4/4
10^{-3}	4/4	4/4
10^{-4}	4/4	3/3
10^{-5}	4/4	4/4
10^{-6}	4/4	4/4
10^{-7}	4/4	3/4
10^{-8}	5/8	6/8
10^{-9}	3/8	2/8
10^{-10}	0/4	1/4
10^{-11}	0/4	0/4

10

From these data, a titer of approximately 10^9 can be calculated for the homogenate. Similar tables were generated for each of the solutions analyzed. From these data, clearance factors for each example were calculated; they are indicated with each example.

Example 1 (for this and the following examples, refer also to Figure 1 showing a diagram of the plasma fractionation method according to Kistler/Nitschmann)

58 ml of human blood plasma were stirred and cooled to 1°C. 0.58 ml of brain homogenate was added. Ethanol was added to a final concentration of 19% with concomitant cooling of the plasma to -5.5°C. After adjustment of the pH to 5.8 perlite was added, and the suspension was centrifuged. The infectivity in the supernatant was reduced by a factor of $\approx 10^5$.

Example 2

40 ml of filtrate a were stirred at -5.5°C. 0.4 ml of brain homogenate was added, followed by addition of ethanol to a final concentration of 40%. Temperature was decreased to -7°C and the pH was adjusted to 5.95. A mixture of perlite and celite was added. The suspension was centrifuged. The infectivity in the supernatant was reduced by a factor of $\approx 10^5$.

Example 3

52 mL of precipitate A were stirred at 1°C. 0.52 ml of brain homogenate was added. Buffer was added and the pH adjusted to 5.1. Water was added, then ethanol to a final concentration of 25%. Temperature was reduced concomitantly to -3°C. Perlite was added and the suspension was centrifuged. The infectivity in the supernatant was reduced by a factor of $\approx 10^6$.

Example 4

33 ml of re-suspended precipitate GG (which contains filter aid from the previous step) were cooled to 4°C. 0.33 ml of brain homogenate was added. The suspension was centrifuged. The infectivity in the supernatant was reduced by a factor of $\approx 10^7$.

Example 5

50 ml of immunoglobulin G solution were stirred at 4°C. 0.5 mL of brain homogenate was added, followed by filter aid (Celite 577). The suspension was centrifuged. The infectivity in the supernatant was reduced by a factor of $\approx 10^6$.

Example 6

33 ml of re-suspended precipitate GG were cooled to 4°C and spiked as described in Example 4. The suspension was centrifuged and the supernatant further treated as in Example 5 (addition of filter aid, followed by
5 centrifugation; volumes adjusted accordingly), but without an additional spike with brain homogenate. After over 200 days of observation, none of the animals injected with the second supernatant showed any signs of disease. This demonstrates that twofold filtration in sequence in the presence of suitable filter
10 aids removes substantially more of the infectious agent(s) than any single filtration would.

Claims

1. A method for separating non-conventional transmissible agents (NCTAs) from a protein solution characterized in that in a solution of a protein susceptible to contamination with NCTAs at least one adsorbent selected from the group consisting of kieselguhr, diatomaceous earth, silicic acid, clay minerals, metal hydroxide, metal oxihydrate, cellulose, perlite, bentonite, and water insoluble synthetic polymers is suspended, for a time of at least 10 minutes during which the obtained suspension is agitated, and subsequently the adsorbent is separated from the protein solution.
2. The method according to claim 1, wherein the adsorbent is separated from the solution of a protein susceptible to contamination with NCTA's by centrifugation or filtration.
3. The method according to claim 1 or 2, wherein the solution of a protein susceptible to contamination with NCTAs is a preparation based on human blood plasma.
4. The method according to claim 1 to 3, wherein the adsorbent is an insoluble metal hydroxide or metal oxihydrate.
5. The method according to claim 4, wherein the adsorbent is magnesium or aluminum hydroxide.
6. The method according to one of the claims 1 to 4, wherein the adsorbent contains aluminum hydroxide gel or cellulose.
7. The method according to claim 1, wherein the adsorbent is diatomaceous earth, perlite, heat expanded perlite, bentonite, or talcum.
8. The method according to claim 1, wherein the adsorbent is present in the form of a gel.

9. The method according to one of the claims 1 to 8, wherein the solution of a protein is susceptible to contamination with NCTAs is contacted at least twice with a fresh portion of the adsorbent.

10. The method of claim 9 wherein the solution is contacted
5 three times with a fresh portion of the adsorbent.

11. The method of one of the claims, 1 to 10, wherein the pH of the suspension is within the range of 4 to 7.

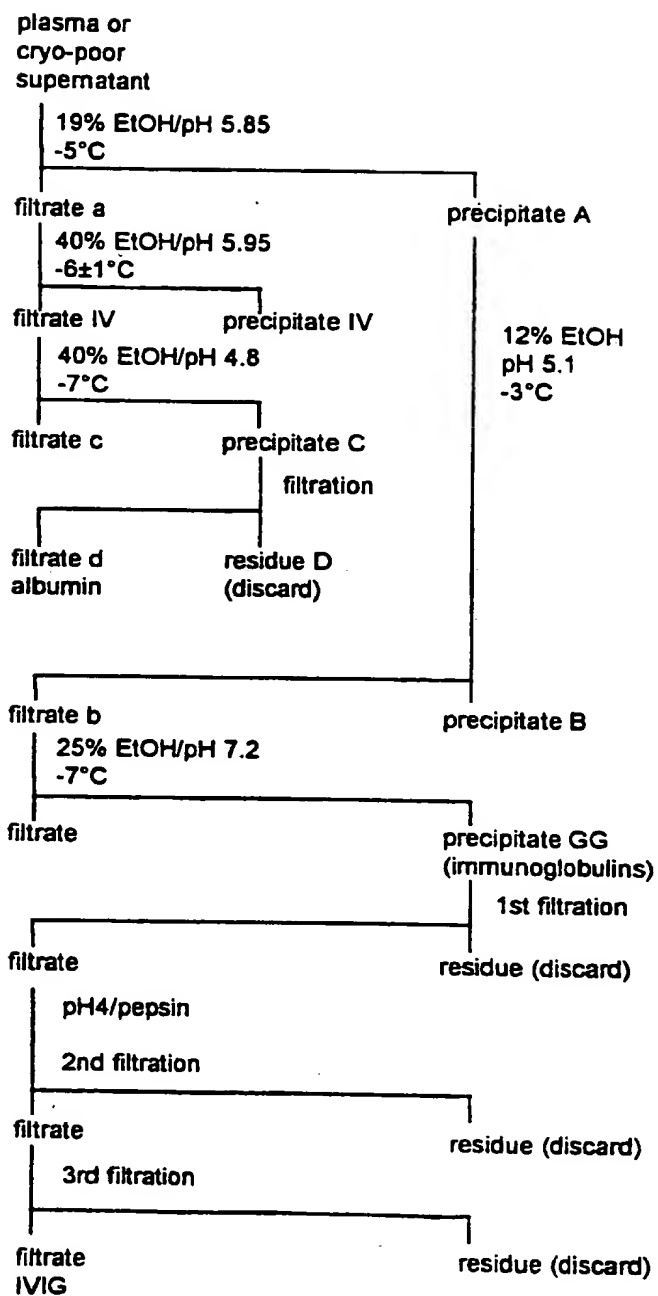

12. The method of one of the claims 1 to 11, wherein one or more of the parameters of the solution are changed at least once during the
10 contact time of the solution with the adsorbent.

13. The method of claim 12, wherein the parameters of the solution are the temperature, the concentration of one or more solutes and the ionic strength.

14. The method of one of the claims 1 to 13, wherein the
15 contact time of the solution with the adsorbent is within the range of 3 min to 48 h, e.g. between 30 min and 12 h or between 3 h and 48 h.

15. The method of one of the claims 1 to 13, wherein the temperature of the protein solution is within the range of 0°C to 20°C and preferably about 2°C.
